The Application of Higher-Order Multivariate Markov Chains to Procedurally Generated Music

29 April 2016

Eric Perkey, Bryce Wilson

Section 002

Abstract

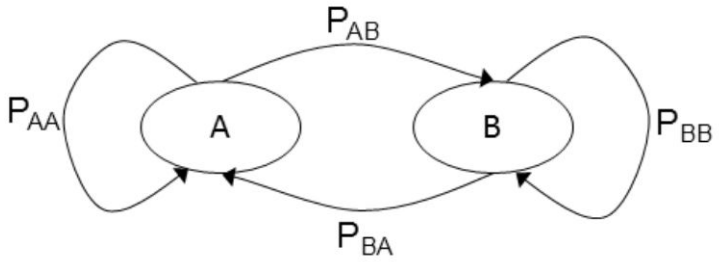
Markov chains are commonly used in modeling many practical systems such as queuing systems, manufacturing systems and inventory systems. If one can model the categorical data sequences accurately, then one can make good predictions and plan in a decision-making process. Markov chains are used most easily with sequences of data that rely on only themselves, such as the letters or words in a sentence, or in our case, notes in a musical piece.

Multivariate chains can be used to model more complicated sets of data. *Higher-order multivariate Markov chains and their applications* by Wai-Ki Ching, Michael K. Ng, and Eric S. Fung (2007) proposes a model for higher-order multivariate Markov chains, which can be used for modeling sequences of data that depend on one another as well as more than one previous state in each sequence. In this paper, we will explore the application of generating music. In a similar fashion to the imitation of Shakespeare using higher-order Markov chains, higher-order multivariate Markov chains could be used to imitate the works of famous composers.

Though difficult to analyze with music theory, the results sound notably improved from a series of random notes. Using a Markov chain as a foundation for procedurally generating music is therefore entirely viable.

Introduction

The simplest form of a Markov chain is one that translates between two states. With two states (defined as A and B) in the state space, there are 4 possible transitions. If it was at 'A' it could transition to 'B' or stay at 'A'. If it was at 'B' it could transition to 'A' or stay at 'B', as shown in Figure 1. In this two state situation, the probability of transitioning from any state to any other state is 0.5.



$$\mathbf{P}=\begin{bmatrix} p_{AA} & p_{AB} \\ p_{BA} & p_{BB} \end{bmatrix}$$

Figure 1: Diagram of two state Markov chain. Matrix P defined as probability matrix based on the states.

We will construct a frequency transition matrix, then by normalizing these matrices, leads us to a "probability matrix" to tally the transition probabilities. Every state in the state space is included once as a row and again as a column, and each cell in the matrix tells us the probability of transitioning from its row's state to its column's state. If the state space adds one state, we add one row and one column, adding one cell to every existing column and row. Higher-order models remember more “history;” additional history can have predictive value.

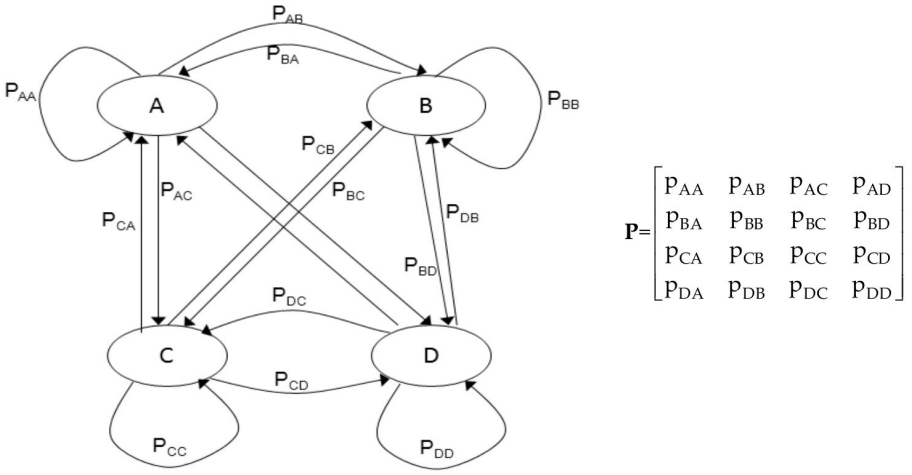


Figure 2: Similar to Figure 2, but with two additional states, creating a more complex Markov chain. Matrix P, again, is defined as the probability matrix for each state switch.

A higher-order Markov chain uses multiple graphs and probability matrices. As before, probability matrices are derived from frequency matrices, but now we keep track of states preceding the previous state. That is, instead of only the last state having an effect on the next state, the last n states have an effect on the next state. This leaves us with n probability matrices.

The next type of Markov chain is a multivariate Markov chain, which uses multiple sequences of data. The probability of a certain sequence going to a certain state depends not only on that sequence's last state, but also some number of other sequences' last states. Now our probability matrix must be made up of other probability matrices. In the same way we keep track of going from state A to state B in one sequence, we want to keep track of going from state M in sequence A to state N in sequence B. In order to keep our probabilities from multiplying, there must also be weights between the sequences. The higher the weight, the more of an effect the corresponding sequence has on the next state. These weights must sum to 1 for all effects on each sequence.

The next logical step is to move to higher-order multivariate Markov chains, which are discussed by Wai-Ki Ching, Michael K. Ng, and Eric S. Fung in their paper. Instead of using a matrix of lists of matrices, they propose a single matrix that will achieve the same effect when multiplied by a single column vector of the current state probability vectors. This model can look n steps back in s sequences.

We will use higher-order multivariate Markov chains to imitate the style of Beethoven's piano sonatas.

Mathematical Formulation

In order to keep the basic exploration simple, the most important notes of each eighth note beat in both hands of a piano piece were used. In addition, only pieces in C major in 4/4 time were considered. In that case, we could represent notes themselves as values rather than keeping track of intervals. Ignoring octaves, each named note was assigned a number, as was a rest, giving 13 states (no distinctions were made between enharmonically similar notes). We decided to choose n to be 16, or to let each note depend on the previous two measures in both hands. The sheet music that was available to us was translated to two sequences. Frequencies and probabilities were then calculated in Mathematica. We decided to set all weights to be equal, again for simplicity. This data was then combined in the format discussed by Ching, Ng, and Fung into the matrix Q. For the sake of space, we do not have an image of this matrix, though the code can be found in the appendices.

In order to generate a new sequence, we were required to begin with sequences of 16 notes with a probability of occurrence greater than 0. To do this, we simply chose the two measures that already existed in our input data. These states made up our initial probability vector X.

We can now find the probabilities of the next states by $QX^{(k)} = X^{(k+1)}$.

Examples and Numerical Results

From $QX^{(0)} = X^{(1)}$ we find the probabilities of the next state in both sequences. Comparing a random number to our new vector allows us to choose a new state based on these probabilities. That new state is recorded in our output and replaces the probability vector we just found with an elementary basis vector for the corresponding state, since we are now certain of the state of the most recent note.

This process was repeated 64 times to give us 64 eighth notes, or 8 measures of music. The data was translated back into sheet music and audio files. Because music is subjective, we also created a couple sequences using only random numbers for a control. While listening, we recommend playing a randomized track before each output in order to make distinctions easier. All tests were produced with the same procedure, weights, steps back, input data, etc…

Figures titled *Random* are simply random notes generated in the same format as the program output by a random number generator. Their purpose is as a control or reference to the outputs of our program. Figures titled *Test* are all outputs of the Markov chain procedure. Each image is accompanied by a link to a midi file that will play the corresponding music. The enharmonic spelling of a note should be considered irrelevant. Because the computer is not attempting to follow the rules of music theory, there is currently no "correct" way to spell the note. Whether a note is written F# or Gb is arbitrary.

Conclusion

Because of the subjectivity of music, it is difficult to argue that our results convey progress without analyzing many outputs with music theory and statistics, but we believe there is a significant difference between the tests and the random notes. Considering these improvements were generated under heavy restriction, we believe it is very possible to use Markov chains to procedurally generate music. Concerning improvements to the program we already have, changing the weights λ could have a dramatic effect, though it would take research to determine which previous states should have the most weight. The position of a note in a measure has a significant effect on whether a note is a rest. We noticed that our program frequently had strange syncopations that existed because the program wasn't predicting based on the beat the note landed on. This could be done with multiple matrices Q, where each Q corresponds to a different position in a measure. Calculating Q is relatively inexpensive relative to generating sequences, so a list of Q's would not be extreme. Adding more attributes such as chords, accents, or other instruments as sequences could be possible by extension of a working algorithm, though that

would increase computation time greatly. And with a Markov chain procedure that works well, an algorithm could be designed around it that adds key changes, time changes, repeats, tempos, and other broader elements of music.

Our results could be a first step to a very complex program with a realistic running time (albeit large) that can imitate musical works. However, an algorithm that uses Markov chains cannot replicate creativity, and a program like this would likely not be used widely. Such a program could possibly be used as inspiration for a composer with writer's block, but it's difficult to tell so early in the technology.
